## 22 Abstract

23 High performance buildings such as zero energy buildings (ZEB) are an important step towards a  
24 reduction in greenhouse gas emissions. Since ZEB may exhibit large differences between demand and  
25 onsite generated electricity, residual electrical loads imposed by the building may fluctuate between  
26 positive and negative values. Furthermore, such buildings can be characterized by large temporal  
27 changes in residual load, commonly caused by clouds passing on a sunny day. Today, electricity grid  
28 operators can easily deal with a single ZEB with this behavior. But what happens if large portfolios of  
29 ZEB have the same behavior? In this study, a highly efficient office building with a total floor area of  
30 8'355m<sup>2</sup> located in Denver, Colorado was designed and simulated using a detailed building energy  
31 modeling approach. Combining the building energy model with a photovoltaic model showed that the  
32 building reached net positive status on an annual basis. Further analysis of residual loads as well as  
33 strategies for their reduction revealed **the limited potential due to the comparatively high shares from**  
34 **interior lighting and equipment in the energy use distribution**. Using a multiple objective optimization  
35 approach for optimizing several simplified electric and thermal storage systems allowed comparing  
36 different strategies for residual load reduction. Although electrical storage may not yet be economical  
37 given today's system costs, it could be shown that the residual loads can be effectively managed and  
38 reduced, while at the same time, an increase in photovoltaic self-consumption can be achieved. The  
39 analysis concludes with the presentation of a multi-objective optimal solution (Pareto front) for a  
40 battery storage model, indicating what utility incentives would be required to achieve cost  
41 effectiveness for a range of battery system price scenarios.

48 Residual Load

# 49 1. Introduction

## 50 1.1 Motivation

51 The building sector in the U.S. consumes approximately 41% of the nation's total primary energy use.  
52 Additionally, the building sector is by far the largest consumer of electricity, representing 74% of  
53 annual electricity sales. Considering that 66% of the total electricity production is coming from fossil  
54 fuels, makes the greenhouse gas footprint of buildings even worse (U.S. Department of Energy 2015).  
55 Undoubtedly, there is a wide range of improvement opportunities. One of them are zero energy  
56 buildings: Using highly efficient appliances, daylight optimized designs, high performance envelopes  
57 and windows reduces their energy consumption to a minimum, while on-site energy production  
58 systems decrease the annual energy consumption to zero or even into positive territory. Aside from  
59 all advantages there is one major drawback: high residual loads (RL). Electricity grid operators who  
60 provide and maintain the electrical grid do not gain a profit at the end of the year, and even worse,  
61 they must ensure grid stability which is jeopardized by the highly volatile residual loads of zero energy  
62 buildings. Extensive literature about the design of zero energy buildings is available (Hall 2014;  
63 Athienitis, O'Brien 2015; Kolokotsa et al. 2011; Judex 2012). The UW Building Energy Research Group  
64 (BERG) for example has over thirty publications about zero energy buildings and related topics (UW  
65 Berg). Furthermore, there are numerous studies ongoing investigating the influences and risks of feed-  
66 in electricity from onsite PV generation as well as distributed and centralized energy storage strategies  
67 aimed at maintaining grid stability (Milo et al. 2011). To the authors' knowledge, no prior work  
68 combined these topics and elaborated a whole building simulation modeling approach in terms of grid  
69 friendliness.

70

71 1.2 Problem Statement

72 High performance buildings such as ZEB are a step towards a reduction in greenhouse gas emissions.

73 Nonetheless, one of their major drawbacks as mentioned above needs deeper examination. Fig. 1

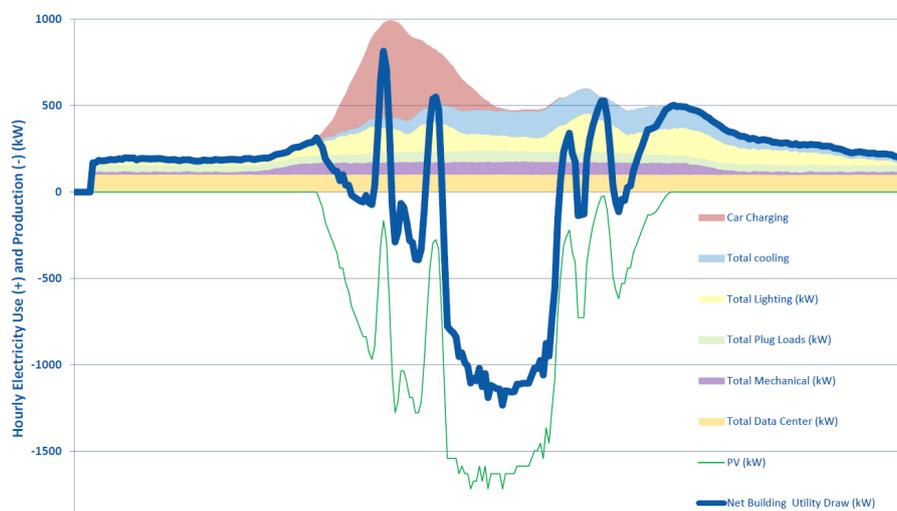

74 shows the uncontrolled residual load profile over one day of the Research Support Facility at the

75 National Renewable Energy Laboratory in Golden, Colorado (Shanti Pless). A peak residual load

76 difference of about 2 MW can be seen at this specific day. Even worse, there are also significant high

77 ramping events in the morning, probably due to clouds, and in the evening when the sun sets.

78

79

80 *Fig. 1. Uncontrolled Load Profile for a Zero Energy Building NREL RSF*

81 1.3 Objectives

82 The first objective was an identification of optimal design approaches for a zero energy building.

83 Hence, different building shapes, envelope alternatives, insulation types, orientations and other

84 variations have been considered for possible improvements. The second objective was an analysis of

85 the dynamic residual electrical loads and appropriate strategies for their mitigation and reduction.

86

87 1.4 Zero Energy Building Definition

88 This work adopts the current official definition of a zero energy building authored by the Department

89 of Energy (DOE): “An energy-efficient building where, on a source energy basis, the actual annual

90 delivered energy is less than or equal to the on-site renewable exported energy.” (U.S. Department

91 of Energy).

92 1.5 Residual Load Definition

93 While the term residual load may have different interpretations, throughout this study the term  
94 residual load is defined as the difference between electricity demand and the on-site electricity  
95 production; positive residual loads imply demand from the grid and negative residual loads feed-in  
96 electricity to the grid.

97

98

99

## 100 2. Methods

101 To achieve the objectives of this study, it was necessary to focus on several different characteristics of  
102 zero energy buildings. Building geometry, orientation, envelope types, fenestration, heating,  
103 ventilation and air conditioning (HVAC) systems, and on-site renewable energy systems are just a few  
104 among them. Since this study will serve as a foundation for future studies and many aspects of building  
105 design had to be considered, a simulation approach was chosen. Because OpenStudio provides an  
106 easy-to-use building simulation environment and additionally is open source it was used as modeling  
107 software. To compare different concepts, the Parametric Analysis Tool (PAT) also provided by the  
108 National Renewable Energy Laboratory (NREL) was adopted. Since OpenStudio does not yet allow  
109 implementing advanced HVAC system controls, the Energy Management System (EMS) for EnergyPlus  
110 was used. The photovoltaic model for the on-site renewable energy production was developed in the  
111 System Adviser Model (SAM) software provided by NREL. It is open source and has a large library with  
112 photovoltaic panels and inverter specifications from various manufacturers. Once the building and the  
113 photovoltaic model was established, the residual loads were assessed. **OpenStudio and EnergyPlus**  
114 **building models provide high accuracy modeling due to the heat balance method for the coupled**  
115 **thermal zones, (U.S. Department of Energy et al. 2015; Zhu et al. 2012). However, since a multiple**  
116 **objective optimization approach was chosen for the residual load reduction strategies and the building**  
117 **simulation required considerable processing power, reduced order models for the heat pump and the**  
118 **storage systems were developed in the technical computing environment MATLAB.**

119 The climate where a building is located has a dominant impact on the design and the U.S. has been  
120 divided into eight primary climate zones (ASHRAE 2010). Each climate zone is grouped by the number  
121 of heating and cooling degree days (HDD65 and CDD50). These climate zones are further subdivided  
122 by three moisture levels, humid (A), dry (B) and marine (C). For each climate zone, different provisions  
123 in the salient standards and codes are enforced. Climate zone 5B is valid for Denver where the  
124 proposed building is located (ASHRAE 2014a). Proper weather data is crucial for building energy  
125 simulation. Fortunately, NREL provides a free library with typical meteorological year (TMY) weather  
126 data for simulation purposes, which can be found in the National Solar Radiation Data Base (NSRDB)

127 archive (NSRDB). It has to be noted that TMY data is not suitable for analyzing worst-case scenarios  
128 **with extreme weather conditions** (NSRDB). In the beginning of the design process, TMY data from the  
129 Denver International Airport was used for simulations. As the design process evolved, data at higher  
130 temporal resolution as described further below had to be used. The dynamic behavior of the electricity  
131 production from the photovoltaic (PV) system is important for subsequent residual load analysis; thus,  
132 a higher resolution weather data was therefore needed. Since one-minute based data was only  
133 available for the location in Golden, Colorado, the solar radiation, temperature and humidity values  
134 for Golden were used in the context building simulation. For the remaining values, TMY data from the  
135 Denver International Airport were used.

136

### 137 3. Simulation Model Development

#### 138 3.1 OpenStudio Building Model

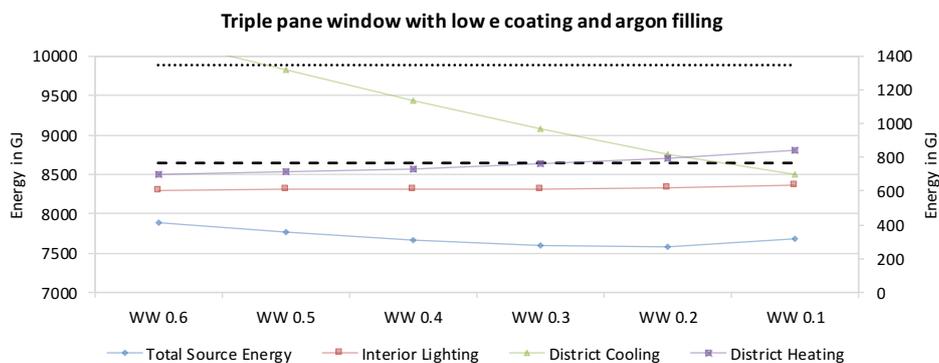

##### 139 3.1.1 Building Envelope

140 The surface-area-to-volume-ratio is an important factor affecting the energy needs of a building. A  
141 large surface area leads to a significant energy exchange between the envelope and the environment.  
142 Hence, the higher the area-to-volume (A/V) ratio, the higher the energy needs should be. Considering  
143 a floor height of 3.8 meters and a total floor area of 8'500 m<sup>2</sup>, the lowest A/V ratio was evaluated for  
144 different number of floors. From 4 to 8 floors, the ratio is about 15%. Reducing the number of floors,  
145 leads to an increase in A/V ratio up to approximately 30% for a single-storey building. Since the  
146 influence of weather impacts, ground heat exchange and other interactions are not considered by the  
147 A/V ratio, a parametric analysis for different number of floors, window-to-wall ratios, aspect ratios and  
148 orientations has been conducted. The simulation for this analysis were highly simplified. **The option**  
149 **“Ideal Air Loads” was used in OpenStudio (NREL 2015), therefore neither a ventilation nor a heating**  
150 **and cooling system had to be designed. In this case, EnergyPlus assumes perfectly met comfort**  
151 **conditions. For the sake of simplicity, no shading and daylight control were considered.** Analyzing the  
152 results from the Parametric Analysis Tool (PAT) revealed a surprising outcome. The single-storey  
153 building has the lowest combined cooling and heating demand. Since this result, **due to the high A/V**  
154 **ratio,** was not expected, a reason for this behavior had to be found. Changing the ground surface  
155 conditions as adiabatic, effected the expected behavior; a taller building has lower cooling and heating  
156 demand than a single-storey building. Thus, the reason for the unexpected results is the strong impact  
157 of the ground heat exchange. **Constant ground temperatures from the EnergyPlus Weather (.epw) data**  
158 **Denver International Airport were used (U.S. Department of Energy et al.).** Considering the land price  
159 in Denver and the use of daylight, further simulations adopted a three-storey building.

160

161 3.1.2 Window-to-Wall Ratio

162 The optimal window-to-wall (W/W) ratio is challenging to choose but essential for a zero energy  
 163 building. An optimum between heating and cooling losses, daylight savings and solar gains must be  
 164 found. Fig. 2 shows the energy needs depending on the W/W ratio. The dashed line illustrates the total  
 165 source energy needs without windows whereas the dotted line shows a baseline case with 40% W/W  
 166 ratio and American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) 90.1-  
 167 2004 window specifications (U-factor 3.12 W/m<sup>2</sup>, SHGC 0.4, VLT 0.31), but without daylight control.  
 168 The total source energies are on the primary y-axis whereas the energy use of the interior lighting,  
 169 district heating and cooling are on the secondary y-axis. As expected, the total source energy needs  
 170 are a lot lower with triple pane windows. Due to the large savings, the designed building was finally  
 171 equipped with triple pane windows. Regarding Fig. 2, the total source energy needs are lowest at 20%  
 172 W/W ratio (U-factor 0.785 W/m<sup>2</sup>, SHGC 0.474, VLT 0.661). Therefore, approximately this ratio was  
 173 adopted in the proposed building design. The fact that daylight also has an important role considering  
 174 employees comfort, would justify percentages higher than the energy optimum.

175  
 176 *Fig. 2. Evaluation of the Window to Wall Ratio*

177

178 3.1.3 Aspect Ratio

179 The aspect ratio (ratio of building length to width) was varied from 1.0 (square) up to 3.0. Since the  
180 cooling and heating energy demand did not change significantly but daylight penetration at the  
181 preferred south and north façade is favored with higher ratios, a ratio of 2.0 was chosen. The  
182 orientation (0° represents a southern orientation) of the building was changed from 0° up to 60°. Since  
183 south-north orientated buildings have better daylight penetration and east and west facing surfaces  
184 are hard to shade effectively, a south orientation was considered in the designed building. Square and  
185 rectangular shapes have less dead space and are cheaper to build compared to other shapes. On the  
186 other hand, wind optimized shapes could have a beneficial impact on the total energy use . Since  
187 Denver does not have constant high wind velocities, the building was designed in a rectangular shape  
188 using the aspect ratio of 2.0. Because Denver features an almost optimal climate for natural ventilation  
189 (dry and low temperatures during the night), an atrium was included in the center of the building.

190 3.1.4 Floor Plan

191 Following the analyses described in the sections given above, the floor plan could be sketched using  
192 common space program assumptions shown in Table 1 (ASHRAE 2014b). In category Others, a printing  
193 room as well as an information technology (IT) room were considered. The total needed ground area  
194 is 2'850 m<sup>2</sup>.

195

### 196 3.1.5 Roof Type

197 Pitched roofs come in a variety of styles, such as gable, cross gable and hipped, all sloped to different  
198 degrees. Their installation cost is usually higher than a flat roof, but since flat roofs need more  
199 maintenance regarding the sealing, the long-term costs are similar. Another important point to  
200 mention is the dead volume. Office buildings usually do not have an attic. Hence, the lost volume  
201 related to the pitched roof cannot be used as effectively as in residential buildings. Since a photovoltaic  
202 system is very likely on a ZEB and pitched roofs are less flexible concerning later orientation changes,  
203 a flat roof was considered for the designed building model.

204

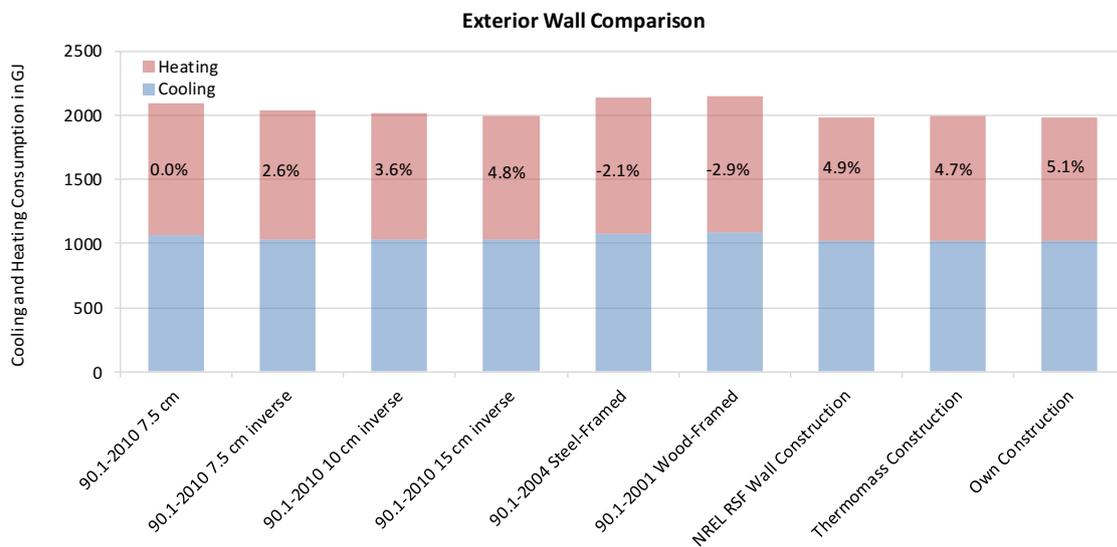

205

### 206 3.1.6 Wall Construction

207 To reach the goal of a zero energy building, the energy demand should be as low as possible but the  
208 building should still be affordable. Exterior walls including their insulation play an important role in this  
209 case. To evaluate the exterior walls, different wall types and insulation thicknesses were compared,  
210 shown in Fig. 3. The first construction uses the OpenStudio default recommendations for an exterior  
211 mass wall according to ASHRAE 90.1-2010 (ASHRAE 2010). This construction consists of an interior  
212 insulation and a concrete mass wall. Since exterior insulations have different benefits such as reduced  
213 condensation problems and the use of thermal mass, the construction layers were switched. Just by  
214 doing so, the combined heating and cooling needs could be reduced by 2.6%. Increasing the insulation  
215 thickness effected a decrease in cooling and heating energy as well. The two other construction types,  
216 as well OpenStudio default recommendations, a steel-framed and a wood-framed wall increased the  
217 energy demand. In order to make a decision on the insulation thickness, different studies on  
218 economical insulation thickness optima were reviewed (Jozsef Nyers, Slavica Tomic, Arpad Nyers 2014;  
219 Çomaklı, Yüksel 2003; Martin Jakob 2004; Nematchoua et al. 2015). Summarizing the literature, an  
220 insulation layer of about 10 cm is considered the optimum economical thickness. One study showed  
221 that if longer payback times were permitted, thicker layers are favored (Martin Jakob 2004). Thermal  
222 mass is another important factor for an exterior wall construction. The higher it is, the more thermal

223 storage capacity is available and this in turn increases comfort, due to slower changing zone  
 224 temperatures. Furthermore, it allows shifting the supplied cooling and heating to economically  
 225 favorable hours. These considerations lead to three additional wall constructions. Thanks to the  
 226 assistance received from a wall construction company, the wall construction previously used in the  
 227 Research Support Facility building on the campus of the National Renewable Energy Laboratory could  
 228 be modeled (U.S. Department of Energy). Moreover, they suggested a construction set located in  
 229 Denver. Considering thermal mass and insulation, a custom assembled construction was introduced as  
 230 well.

231

232

233 *Fig. 3. Exterior Wall Performance Comparison including their U-Value*

234 The wall construction company provided one overall R-Value which also considers wall connectors.  
 235 Since OpenStudio requests values for each layer, they were evaluated using literature for the material  
 236 properties (Fundamentals 1997). Comparing the evaluated with the provided R-Value showed an error  
 237 of about 3%, which was assumed to be sufficiently accurate. Fig. 4 shows the selected wall construction  
 238 **suggest by Thermomass.**

239

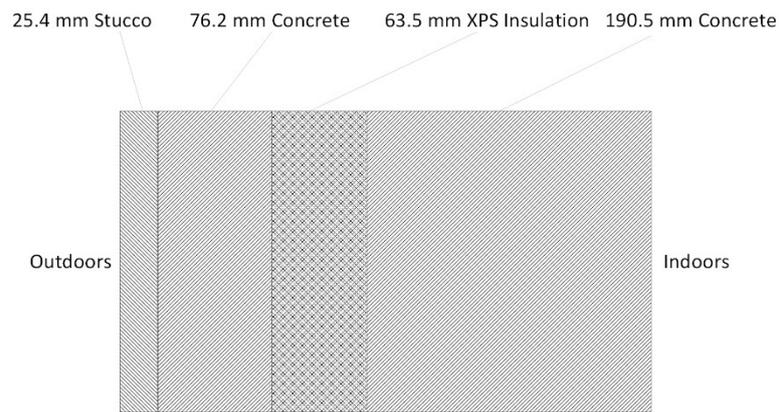

Fig. 4. Suggested Wall Construction

240

241

242 The exterior roof was selected following the Advanced Energy Design Guide from ASHRAE that  
 243 recommends an R-Value greater than  $4.56 \text{ m}^2\text{K/W}$  for climate zone 5 (ASHRAE 2014b). A pre-  
 244 assembled construction from the building component library (BCL) with a matching R-value was  
 245 adopted in the building model (Building Component Library). **The construction consists of three layers:**  
 246 **a metal decking, an insulation layer with a thickness of 26 cm and a roof membrane.**

### 247 3.1.7 Thermally Activated Building Systems (TABS) Floor Construction

248 OpenStudio uses internal source constructions to model radiant floor and ceiling systems. Therefore,  
 249 each surface which is part of the radiant cooling or heating system needs to be assigned to this  
 250 construction set. The different construction layers must be manually specified in OpenStudio.  
 251 Furthermore, the location of the hydronic piping and the temperature sensor must be assigned to the  
 252 desired layer. The implemented internal source construction sets are shown in Fig. 5 and Fig. 6. Using  
 253 an application handbook and a TABS control guide developed by a building automation manufacturer  
 254 lead to the selected interior floor thickness of 203 mm (Siemens; Faktor Verlag AG - Architektur,  
 255 Technik. Energie. Informationen zur Nachhaltigkeit am Bau - TABS-Tool). The piping as well as the  
 256 temperature sensor were located in the center. No insulation layer was added to the interior  
 257 construction set. The construction facing the ground consists of a 102 mm concrete layer followed by  
 258 a 25 mm insulation layer and another 102 mm concrete layer. **Thermally activated building systems**  
 259 **(TABS) are typically operated at low hot water and high chilled water supply temperatures. Since heat**  
 260 **pumps are more efficient in this context, the decision was made to use this system.**

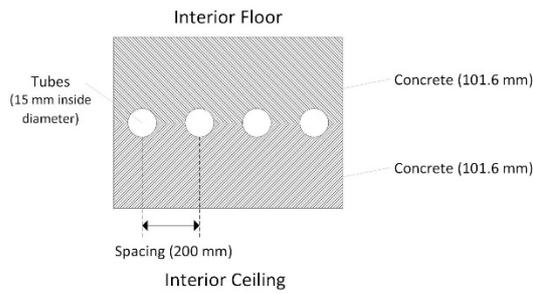

Fig. 5. Internal Source Construction (interior)

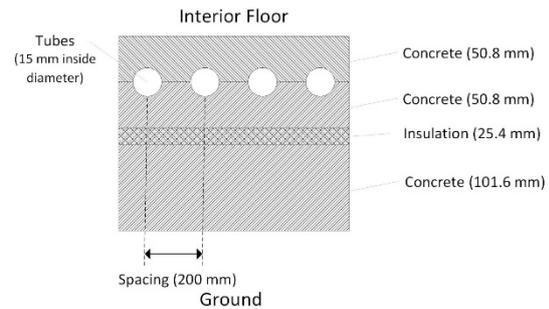

Fig. 6. Internal Source Construction (exterior)

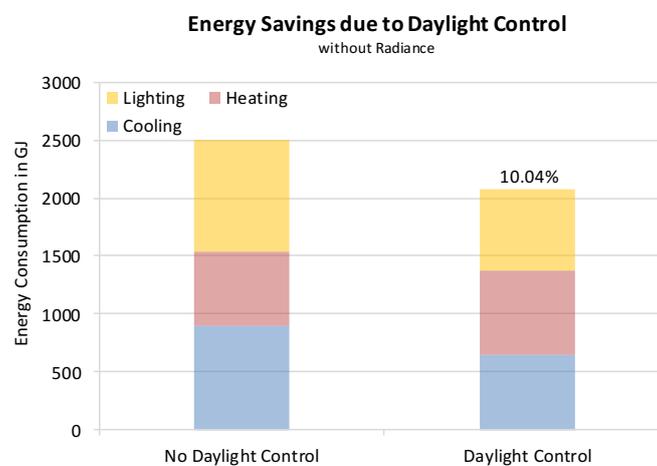

261

### 262 3.1.8 Daylight Analysis

263 Energy use for electrical lighting represent a significant share of the total energy consumption of a  
 264 building. At the same time, it is known that daylight has an important impact to human health and can  
 265 increase productivity significantly. The fact that north and south facing offices provide the best daylight  
 266 conditions was already considered by selecting an appropriate building aspect ratio. OpenStudio has a  
 267 dedicated tool for daylight analysis: The daylight analysis tool Radiance is based on raytracing and has  
 268 recently been integrated with OpenStudio (Rob Guglielmetti). The downside of the accuracy of  
 269 raytracing are its high computational requirements, making it currently impossible to simulate the  
 270 entire building at once. Hence, several representative zones had to be selected and simulated  
 271 separately. At least one zone per orientation must be selected to get a robust analysis of daylight  
 272 availability. Obviously, the more zones are simulated the more accurate the total savings estimates  
 273 are. Simulations showed that interior zones are not affected significantly if interior windows are  
 274 applied and both zones (exterior and interior) are simulated together. This outcome reduced the  
 275 simulation effort significantly. Radiance provides three different daylight metrics. Daylight autonomy  
 276 (DA), continuous daylight autonomy (cDA) and useful daylight illuminance (UDI). By using eight  
 277 representative zones it was possible to compare several different measures to increase and optimize  
 278 daylight savings. Based on the more accurate evaluation algorithm of Radiance those results are more  
 279 accurate than the radiosity (split flux) based approach that OpenStudio uses in the EnergyPlus engine.

280 As mentioned above, the annual electrical lighting distribution of the entire building could not be  
281 evaluated by the Radiance approach. Therefore, the best options evaluated with the Radiance  
282 approach were applied to the whole building model and simulated again. Table 2 shows the tests  
283 options for daylight optimization for which the illuminance set point was set at 500 lux. Fig. 7 shows  
284 the site energy savings with total annual savings of 10%. The difference between the Radiance and  
285 radiosity based approaches was smaller than 1%, so the inaccuracy was deemed acceptable.

286

287

288

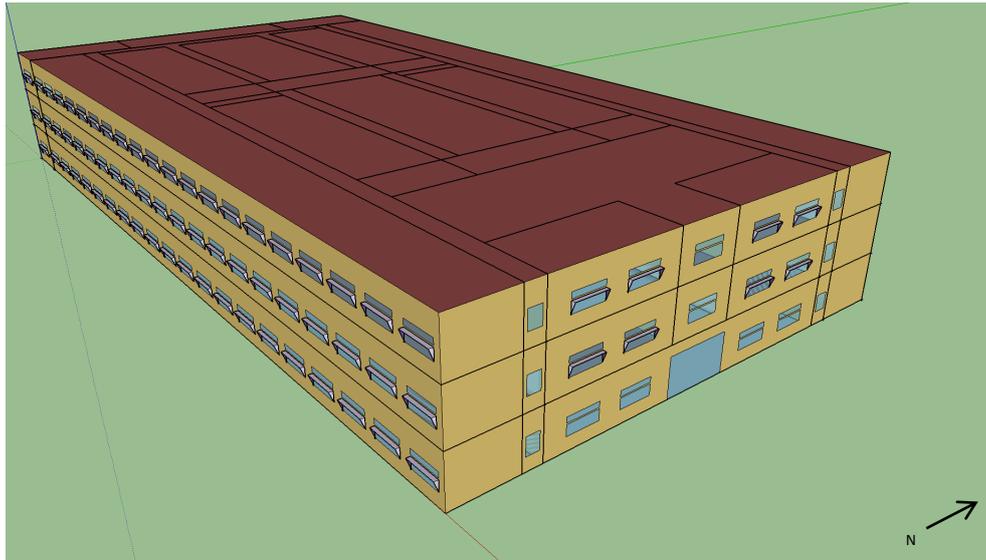

Fig. 7. Energy Savings due to Daylight Control

289

### 290 3.1.9 Final Building Design

291 The findings described in Sections 3.1.1 to 3.1.7 resulted iteratively to the three-dimensional building  
292 model. Fig. 8 shows the final building model with the entrance on the east side. Using the same window  
293 and shading objects for the whole building is favorable for cost reasons. In total, 6'638 m<sup>2</sup> are  
294 conditioned and 1'718 m<sup>2</sup> are unconditioned. The south and north façade have a window-to-wall ratio  
295 of 22% whereas the east and west façade have one of 15%.

296

297  
298  
299  
300  
301

*Fig. 8. Final 3-D Building Model*

### 302 3.1.10 HVAC System

303 Heating, ventilating and air conditioning (HVAC) systems provide heating, cooling, humidification,  
304 dehumidification and air quality control to satisfy the occupant needs. There are two main system  
305 options: Central HVAC systems which are, for example used in commercial office buildings and  
306 decentralized HVAC systems, such as an individual room air conditioner, as they can be found in motels  
307 **or smaller office buildings**. Even though decentralized HVAC system can be appropriate for very specific  
308 applications, higher maintenance costs, construction constraints, noise, and commonly a lower overall  
309 efficiency make them second choice for newly constructed buildings. Due to the stated reasons, a  
310 decentralized system was not considered in the designed building (U.S. Department of Energy; Henze  
311 2016).

312 **Due to the low heating and high cooling supply water temperatures, a** thermally activated building  
313 system (TABS) combined with a heat pump can be one of the most efficient HVAC system  
314 configurations available; therefore, a TABS combined with a ground source heat pump was selected  
315 for the designed building (Informationsdienst). In order to meet air quality standards, a demand  
316 controlled ventilation, dedicated outdoor air system (DOAS) **with a heating and cooling heat recovery**  
317 **system was used**. It provides the occupied zones with 22°C pre-tempered fresh air. In addition to the  
318 DOAS, natural ventilation was implemented for night pre-cooling. Since office buildings have very low  
319 service hot water needs, those systems offer a lower potential for energy savings, but nevertheless a  
320 heat pump water heater was used. Fig. 9 shows a simplified schematic of the modeled HVAC system.  
321 The key performance metrics of the proposed building are described in Chapter 4.

322

323

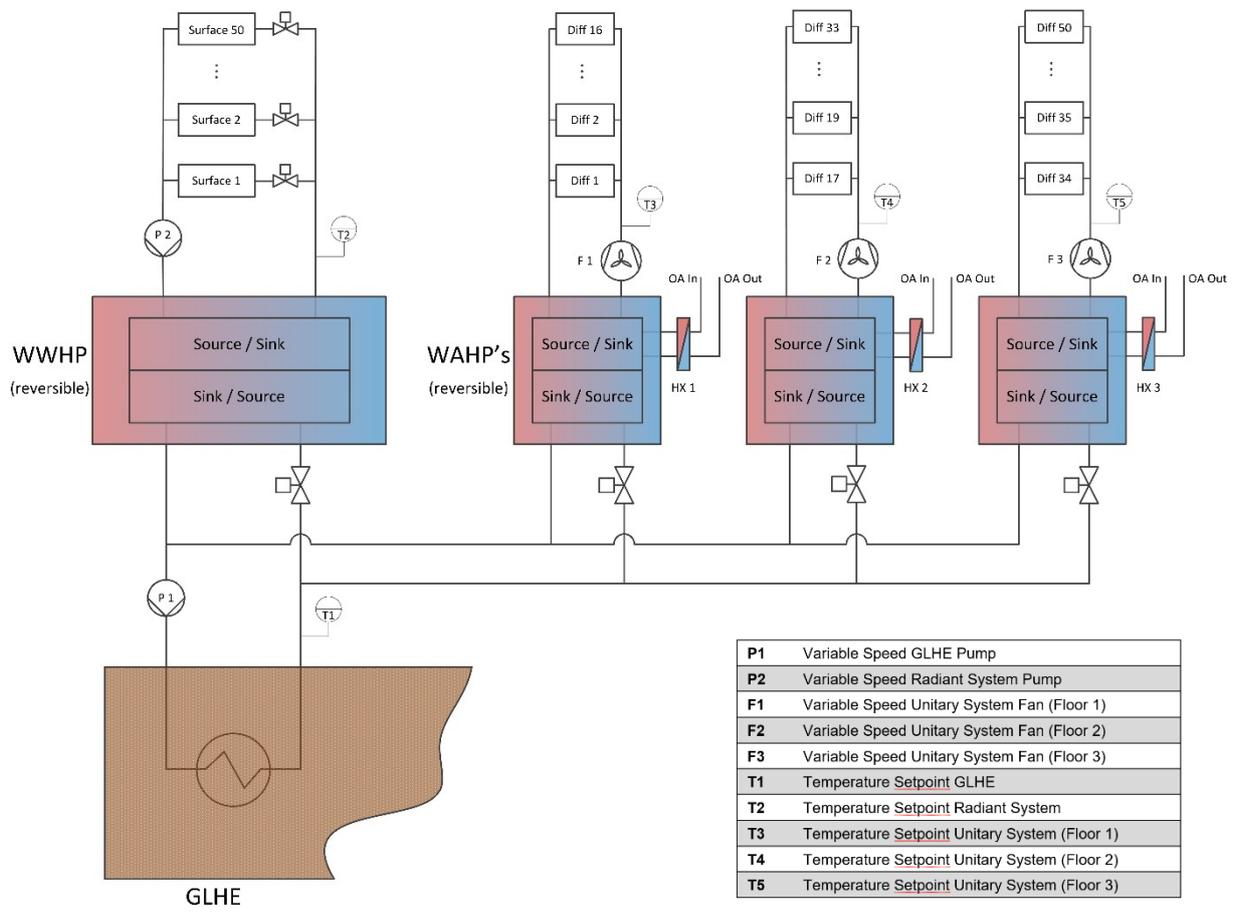

Fig. 9. HVAC Schematic

324

325 3.2 On-Site Renewable Energy

326 ZEB's, as described in Section 1.5, have to have a zero or a negative source energy balance on an annual  
327 base, requiring on-site renewable energy generation such as solar or wind power. In this study, only a  
328 photovoltaic system was considered. The PV system was modeled with the System Advisor Model  
329 Software (SAM) (System Advisor Model 2016). It is capable of simulating various types of on-site energy  
330 production plants but for this project only the photovoltaic tool was used. Since hundreds of PV panel  
331 and inverter specifications from several suppliers are preloaded, it is a lot easier to model the system.  
332 SAM allows the user to set the numbers of strings and rows manually. By selecting the orientation and  
333 the ground coverage ratio, SAM considers self-shading losses. Furthermore, it was possible to consider  
334 the adjacent buildings as shading objects. Selecting soiling and balance-of-system losses completes the  
335 technical design of the system. The effects of dynamic weather changes on the electricity production  
336 is crucial for residual load analysis, therefore weather data at higher temporal resolution had to be  
337 used for the simulation. Fortunately, minute-by-minute data was available from the solar radiation  
338 research laboratory (BMS) at NREL (Stoffel, Andreas 1981). The photovoltaic array was designed in an  
339 iterative approach by comparing the total on-site electricity production and the annual electricity  
340 demand. It turned out that the annual production of the roof array was not high enough to achieve  
341 ZEB status. Therefore, the south, east and the west façades were also considered as solar collection  
342 area. Since the vertically mounted façade panels have a lower efficiency, cheaper thin film panels were  
343 considered there. On the roof, 612 PV panels with an installed capacity of 200 kW and on all three  
344 facades combined 954 thin film PV panels with an installed capacity of 112 kW were considered. **The**  
345 **characteristics of the PV system are shown in Table 3. The differences of the energy production from**  
346 **the east and west façade are explained due to shading from surrounding buildings.**

347

348

349

### 350 3.3 Reduced Order Model for Controls Analysis

#### 351 3.3.1 Controls

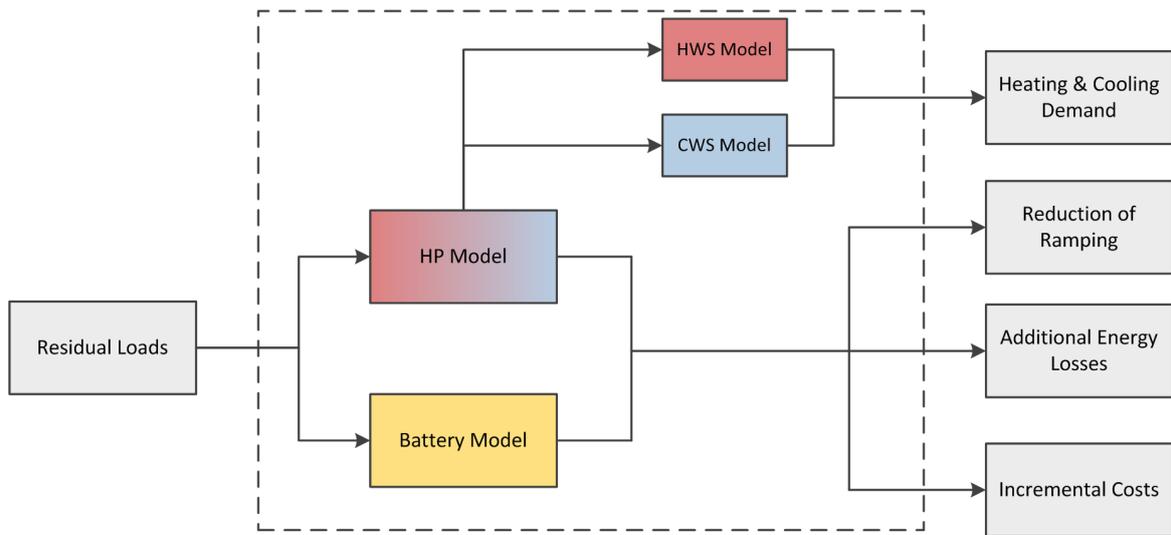

352 Fig. 10 shows a schematic of the reduced order model developed for the residual load reduction. The  
353 residual loads were used as input signal whereas the heating and cooling demand, the reduction of  
354 ramping, the additional energy losses and the incremental costs are use as output signals. Inside the  
355 model, the heat pump (HP), the hot and cold water storage systems (HWS & CWS) as well as the battery  
356 are illustrated. The applied control strategies for the storage systems and heat pump only consider  
357 current and past data, i.e., involve no prediction. Thus, the residual load at each time step was used as  
358 the input signal. As soon as the residual load becomes negative, the state-of-charge (SOC) of the HWS,  
359 CWS and the battery was checked, and depending on their state-of-charge (SOC), charging, discharging  
360 or a dormant state of that was selected. For the thermal storage system, an SOC from 0 to 1 and for  
361 the battery an SOC from 0.2 to 0.85 was considered. The battery is, because it can be charged and  
362 discharged independently from the heating and cooling demand, is more flexible than the thermal  
363 energy storage; therefore the HWS and CWS control was prioritized. The thermal storage systems were  
364 discharged depending on the heating and cooling demand. As soon as their SOC fell below 10%, the  
365 heat pump was turned on and tracked the demand power. This control ensured that the comfort level  
366 was never jeopardized. The battery was discharged if the SOC was in between the mentioned range  
367 and the residual load was above zero.

#### 368 3.3.2 Model

369 The heat pump was modeled as having a constant coefficient-of-performance (COP). Thus, the input  
370 electrical power multiplied by the rated COP leads to the heating, respectively, cooling delivered.  
371 Neither a start-up time nor a minimum run time was considered. The hot water as well as the chilled  
372 water storage was modeled by aggregating the HP's output energy for each time step. A heat  
373 transmission loss term is adopted to take heat losses and gains through the storage tank envelope into  
374 account. Neither loading nor unloading effects were considered. Because the reduced order model has  
375 no interconnection with the thermal building model, heating and cooling demand could not be shifted.

376 The battery was modeled by integrating the power which was transmitted. A charging and discharging  
377 rate of 0.5 C was considered. An alternating current to alternating current (AC-AC) as well as an  
378 alternating current to direct current (AC-DC) inverter efficiency of 95% was assumed. Even though the  
379 constant losses of a battery are low over 24 hours they were also considered. No battery degradation  
380 and cycle stability was considered.

381

382

383 *Fig. 10. Reduced Order Model for Residual Load Reduction*

384

### 385 3.3.3 Multiple Objective Optimization

386 A comparison between three different strategies was made to find the most appropriate solution. A  
 387 thermal storage only, battery only, and a combined configuration were compared. The thermal only  
 388 storage case could, due to the low heating and cooling demand, not significantly reduce the ramping.  
 389 To compare the battery only and the combined configuration, a multiple objective optimization was  
 390 performed. The thermal storage size and the battery capacities were used as decision variables ( 5 ).  
 391 The ramping ratio, which is used for quantifying the fluctuations of the residual load time series,  
 392 incremental investment costs and the energy losses were selected as objective functions ( 2 ) - ( 4 ).  
 393 The optimization problem is defined as in ( 1 ).

394

$$\min_{\mathbf{x} \in X} (f_1(\mathbf{x}), f_2(\mathbf{x}), f_3(\mathbf{x})) \quad (1)$$

$$f_1(\mathbf{x}) = \left( \frac{\sum_k^n |P_k^*(\mathbf{x}) - P_{k-1}^*(\mathbf{x})|}{\sum_k^n |P_k - P_{k-1}|} \right) \quad (2)$$

$$f_2(\mathbf{x}) = (C_{Therm} \mathbf{x}(1) \mathbf{x}(1)^{-0.3464} + C_{Therm} \mathbf{x}(2) \mathbf{x}(2)^{-0.3464} + C_{Batt} \mathbf{x}(3) \mathbf{x}(3)^{-0.1}) \quad (3)$$

$$f_3(\mathbf{x}) = (E_{Therm, Loss}(\mathbf{x}(1)) + E_{Therm, Loss}(\mathbf{x}(2)) + E_{Batt, Loss}(\mathbf{x}(3))) \quad (4)$$

$$\mathbf{x} = [V_{Cool}, V_{Hot}, C_{Batt}]^T, \quad \begin{cases} V_{Cool} \in [0, 100] \\ V_{Hot} \in [0, 100] \\ C_{Batt} \in [0, 2500] \end{cases} \quad (5)$$

395

396  $f_1(\mathbf{x})$  is the first objective function where the new ramping is divided by the old ramping; a time step  
 397  $k$  of 15 minutes was considered for a full year ( $n$ ).  $f_2(\mathbf{x})$  considers the incremental costs of the two  
 398 thermal and the battery storage. Specific costs of 3'500 \$/m<sup>3</sup> ( $C_{Therm}$ ) with an exponential scaling term  
 399 of -0.3464 were selected for the thermal storages (Vogelsanger et al. 2008). The scaling effect  
 400 represents a nonlinear price trend if the storage size is increased. For the battery, a specific price of  
 401 1'000 \$/kWh with an exponential scaling term of -0.1 was considered (IRENA 2015).  $f_3(\mathbf{x})$  considers  
 402 the additional energy losses for both the thermal energy and the battery storage systems depending  
 403 on their storage capacity. Thus, the larger the thermal storage or the battery is selected, the greater  
 404 the energy losses that will occur. For the thermal energy storage, a specific loss of 10 W/m<sup>2</sup> was

405 selected (AGFW 2015). Losses for the battery were considered with 5%/24 hours (Buchmann 2016).  $x$   
406 is a vector with the three decision variables including  $V_{Cool}$  as the cold water storage volume in cubic  
407 meters,  $V_{Hot}$  as the hot water storage volume in cubic meters, and  $C_{Batt}$  the battery capacity in  
408 kilowatt hours.

409

410

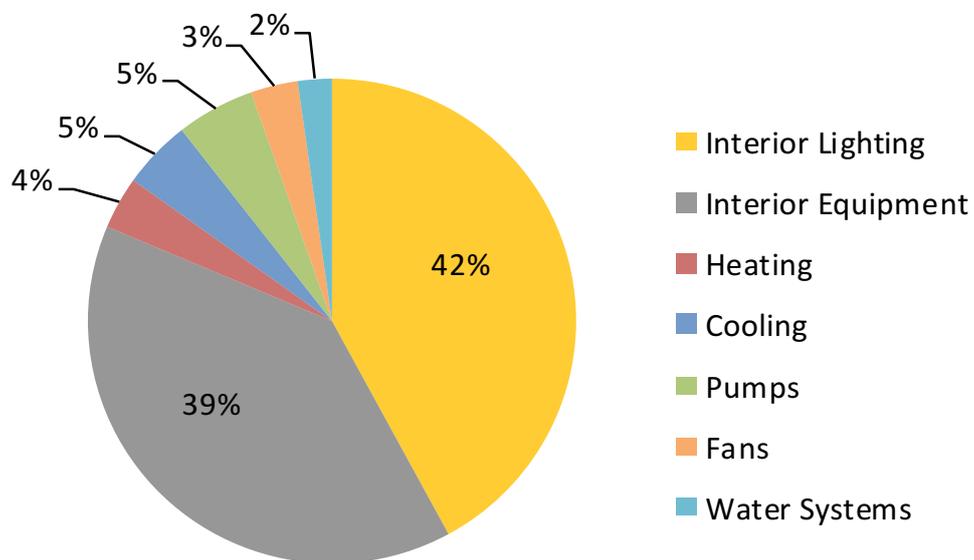

411

412 4. Results and Discussion

413 4.1 Zero Energy Building Model

414 Table 4 shows the key performance metrics of the proposed building, while Fig. 11 illustrates the  
415 distribution of the annual site energy use. It is remarkable to note that all conditioning systems  
416 combined (heating, cooling and fans) only have a share of 17%. This indicates, on one hand, that the  
417 designed building is indeed very efficient, on the other hand, it lets one recognize that the potential  
418 for residual load reduction through demand side management (DSM) is low. Even though the  
419 Advanced Energy Design Guide (AEDG) was used for lighting and equipment, they account for 81 % of  
420 the annual energy use. **It can be argued, that the used energy needs from the AEDG are still too high  
421 for interior lighting and equipment but since the specific energy needs were in a plausible range, no  
422 further efforts were mad to reduce this energy needs.** Because office buildings have low service hot  
423 water use, the low energy consumption was expected.

424

425

426 *Fig. 11. Annual Energy Use Distribution in kWh/m<sup>2</sup>*

427

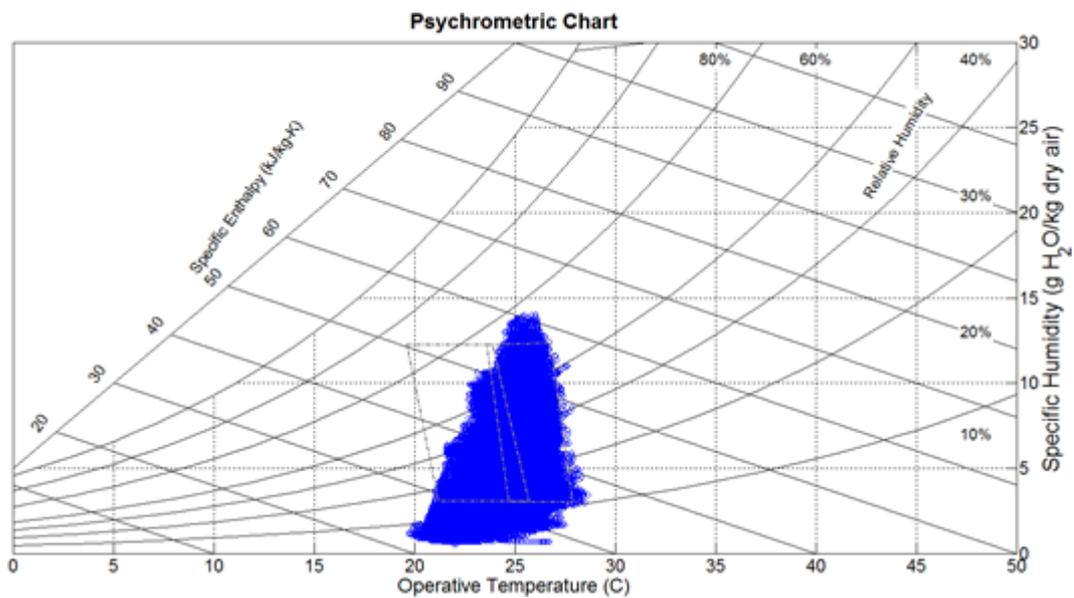

428

429

430

431 Fig. 12 is a psychrometric chart and shows the comfort level of all conditioned zones during occupied  
432 hours at an hourly time step. The two dashed rhomboids are illustrating the comfort zones for summer  
433 and winter. The control of a TABS is quite complex: Using constant supply temperatures and a  
434 simplified control strategy did not allow for an effective setback during unoccupied hours.  
435 Nevertheless, it was possible to control the radiant system so that the comfort levels were met almost  
436 during the whole year. The very dry climate in Denver explains the low relative humidity. The slightly  
437 too high relative humidity values on the top right corner of the summer comfort zone are caused by  
438 the restrooms as well as the meeting rooms, whereas the outliers on the right side are only caused by  
439 the closed offices.

440

441

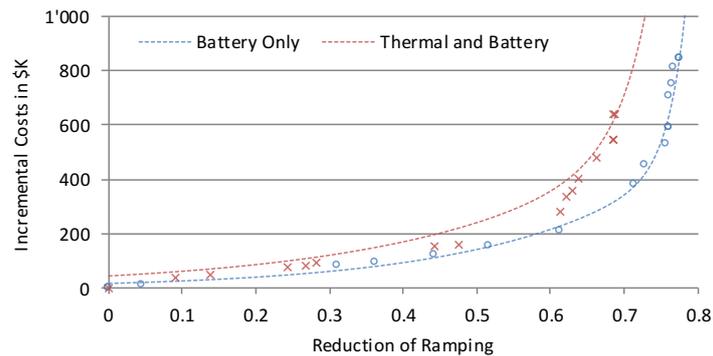

442

Fig. 12. Annual Comfort Chart during Occupied Hours

443

444 4.2 Reduced Order Model

445 Fig. 13 shows the Pareto fronts of both configurations. The Pareto front represents the trade-off  
446 among the different objective functions. These points are called non-inferior or non-dominated points  
447 (Caramia, Dell'Olmo 2008). The points on the Pareto front indicate the final optimization results  
448 whereas the dashed lines represent the exponential fit. Surprisingly, as it can be seen in Fig. 13 the  
449 combined configuration is more expensive at every reduction of ramping compared to the battery  
450 only. One reason for that may be the fairly high losses of the thermal energy storage system. Since one  
451 objective function minimizes them, the battery only configuration always performs better. According  
452 to the outcomes of this comparison, the battery only configuration was selected for further techno-  
453 economic analyses. The impact of a smaller HP in combination with a thermal storage as well as  
454 redundancy aspects have not been considered.

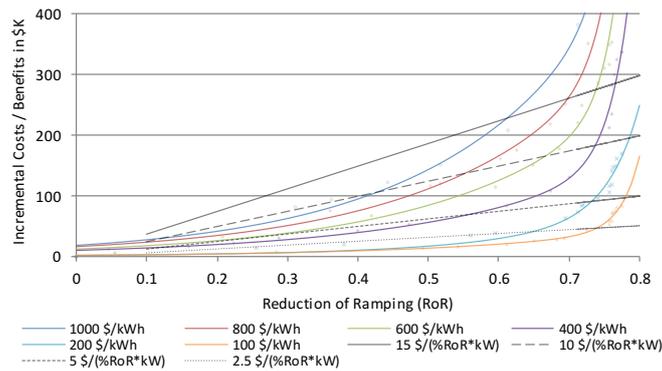

455  
456

Fig. 13. Pareto Front Costs

457 The Pareto fronts in Fig. 13 clearly show that a reduction of ramping can be achieved by using a storage  
458 system. Nevertheless, such a system is only cost effective if there is an additional economic benefit for  
459 the building owner. According to current literature (Merei et al. 2016; Kosten für PV-Stromspeicher -  
460 Wirtschaftlichkeit im Detail), battery systems are not quite economical today. This statement does not  
461 include systems which are subsidized nor does it include systems where DSM is used for increasing the  
462 self-consumption rate. **More detailed information about the potential value of battery storage can be**  
463 **found in the comprehensive report from the Rocky Mountain Institute** (Rocky Mountain Institute  
464 2015). One paper even considered retail electricity prices of 25ct/kWh and feed-in compensations as  
465 low as 2.5ct/kWh. The configuration with storage could only show its profitability when battery system

466 prices are below 200\$/kWh (Merei et al. 2016). Since the impact of ramping caused by ZEB is not  
 467 significant yet, no literature related to the value of ramping reduction incentives could be found.  
 468 Therefore, the optimization problem was conducted several times with different battery system costs  
 469 (colored curves in Fig. 14). While utilities are currently not rewarding customers for a reduction of  
 470 ramping, in the future this could become an option for them when feed-in power from decentralized  
 471 electricity production increases rapidly. Fig. 14 shows the Pareto front family with four linear benefit  
 472 curves (hypothetical incentives paid by the utility). Since a ZEB with a large PV system requires a larger  
 473 battery system to adequately reduce ramping, the benefits depend on the PV system's peak installed  
 474 power. In this study, neither the electricity price nor the feed-in compensation were considered. The  
 475 incremental costs are investments cost.

476  
477 *Fig. 14. Pareto Front Family Battery System*

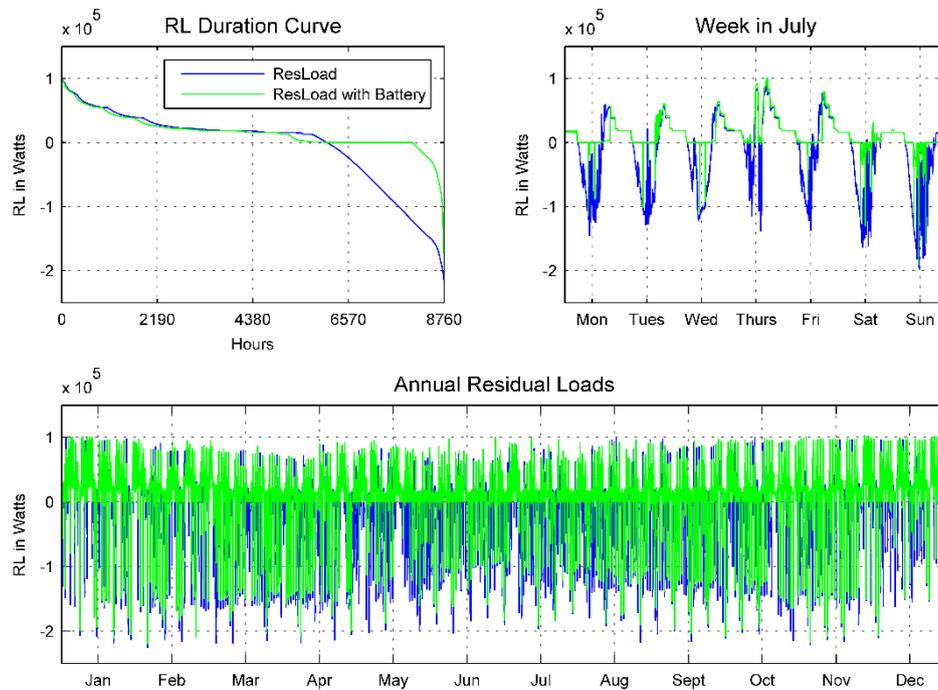

### 478 4.3 Residual Loads

479 The results from the building simulation as well as the PV system model allowed a deeper examination  
 480 of the changes in residual loads. Fig. 15 illustrates the annual and weekly residual loads as well as the  
 481 residual load duration curve. For the weekly graph, a typical week in July was considered. Due to the  
 482 combination of roof and façade mounted PV panels, no production drop can be noticed in winter.  
 483 Subtracting the PV production from the total consumption, leads to an annual PV overproduction of  
 484 34 MWh. Hence, the designed building is not just net zero, it is net positive.

485  
486

487 Even though today it may not be economical to purchase a battery system in combination with the PV  
488 system, a case study was used to show the effect on the residual loads. A capacity of 250 kWh which  
489 reaches a reduction of ramping of 50 % was selected. Fig. 15 reveals the differences in residual loads  
490 with and without battery storage. Because no predictive control strategy was considered and because  
491 the selected battery capacity was not sufficiently large, the peak demand as well as the peak feed-in  
492 power could not be lowered. Nevertheless, the hours of negative residual loads, where electricity is  
493 feed into the grid could be reduced by 1948 hours. This is a very significant reduction by a factor of  
494 3.6.

495

498

499

## 500 5. Conclusion

501 Though OpenStudio does not provide the same functionality as EnergyPlus yet, it was possible to  
502 design and simulate a zero energy building with an advanced HVAC system in the OpenStudio  
503 environment. Combining the building model with a photovoltaic model showed that the proposed  
504 building not only reaches net zero, it even reaches net positive status. Further analysis of residual loads  
505 as well as strategies for their reduction, **showed the limited potential due to the comparatively high**  
506 **shares from interior lighting and equipment to the end energy use breakdown.** Using a multiple  
507 objective optimization approach in combination with a simplified storage model allowed comparing  
508 different control strategies for residual load reduction. The Pareto front family illustrates which  
509 monetary incentives would be required at different battery storage prices to achieve profitability of a  
510 battery storage system.

511

### 512 5.1 Future Work

513 **While the main objectives have been achieved, there are open questions and opportunities for**  
514 **improvements.** Since the building model was quite complex, it would make sense to reduce the  
515 complexity such that the whole HVAC system could be included in the residual load reduction strategy  
516 or the entire model could be optimized. **One possibility would be a reduction in the count of thermal**  
517 **zones or the adoption of a reduced order model. To maintain a high level of accuracy, the reduced**  
518 **order model could also be trained with data taken from the whole building model.** At this point the  
519 storage model and its control are highly simplified; further analysis would therefore focus on a more  
520 detailed model and control. **Additionally, different control strategies should be elaborated and**  
521 **compared. In this respect, a sensitivity analysis could help identifying the dominant factors. Residual**  
522 **load swings due to widespread construction of ZEB's may pose a risk for regional transmission**  
523 **operators (RTO) and utilities in the future, and thus, a collaboration with these entities could help**  
524 **identifying key risks and possible solutions for individual ZEB's or portfolios thereof.**

<b>Total Source Energy</b>	1'175'869 kWh	141.50 kWh/ m <sup>2</sup>
<b>Total EUI</b>	-	44.68 kWh/ m <sup>2</sup>
<b>Interior Lighting</b>	157'081 kWh	18.80 kWh/ m <sup>2</sup>
<b>Interior Equipment</b>	146'628 kWh	17.55 kWh/ m <sup>2</sup>
<b>Heating</b>	13'069 kWh	1.56 kWh/ m <sup>2</sup>
<b>Cooling</b>	17'114 kWh	2.05 kWh/ m <sup>2</sup>
<b>Pumps</b>	19'336 kWh	2.31 kWh/ m <sup>2</sup>
<b>Fans</b>	11'642 kWh	1.39 kWh/ m <sup>2</sup>
<b>Service Hot Water</b>	8'419 kWh	1.01 kWh/ m <sup>2</sup>
<b>EUI Conditioning</b>	-	7.32 kWh/ m <sup>2</sup>

629 List of Figures

630

631 Fig. 1. Uncontrolled Load Profile for a Zero Energy Building NREL RSF..... 4

632 Fig. 2. Evaluation of the Window to Wall Ratio..... 9

633 Fig. 3. Exterior Wall Performance Comparison including their U-Value ..... 12

634 Fig. 4. Suggested Wall Construction ..... 13

635 Fig. 5. Internal Source Construction (interior)..... 14

636 Fig. 6. Internal Source Construction (exterior) ..... 14

637 Fig. 7. Energy Savings due to Daylight Control ..... 15

638 Fig. 8. Final 3-D Building Model..... 16

639 Fig. 9. Simplified HVAC Schematic..... 18

640 Fig. 10. Reduced Order Model for Residual Load Reduction..... 21

641 Fig. 11. Annual Energy Use Distribution in kWh/m<sup>2</sup> ..... 24

642 Fig. 12. Annual Comfort Chart during Occupied Hours ..... 25

643 Fig. 13. Pareto Front Costs ..... 26

644 Fig. 14. Pareto Front Family Battery System ..... 27

645 Fig. 15. Residual Loads with Battery System (normalized)..... 28
